ABSTRACT<br>A New Photometric Redshift Method for Galaxies with $0.01<\mathrm{z}<0.03$<br>Jackson Steele<br>Department of Physics and Astronomy, BYU<br>Bachelor of Science

We typically measure the redshift for distant galaxies using spectroscopy. Although spectroscopy is highly accurate, it requires the use of large telescopes (the time on which is limited). Photometric redshift, another technique, is highly imprecise but can be done on much smaller telescopes. We have created a new method to measure redshift photometrically that is an order of magnitude more precise than other photometric redshift techniques. To do this, we use three specialized narrow-band filters: two filters with variable (linear) transmission that are sloped oppositely (called 'ramp' filters), and a third 21 nm FWHM filter to measure the continuum. These isolate the $\mathrm{H} \alpha$ emission-line for galaxies with $0.01<z<0.03$. Because the transmission is variable in our ramp filters, the brightness of $\mathrm{H} \alpha$ in each filter is a function of the redshift. We have tested this method observationally with 16 Seyfert galaxies and computationally with 197 emission-line galaxies. We are able to predict the redshift with a standard error of $572 \mathrm{~km} \mathrm{~s}^{-1}$. This error decreases for galaxies with stronger $\mathrm{H} \alpha$ emission, and we find that the error drops to $252 \mathrm{~km} \mathrm{~s}^{-1}$ if the $\mathrm{H} \alpha$ equivalent width is over $40 \AA$.

Keywords: photometric redshift, SDSS, distance measurements

## ACKNOWLEDGMENTS

I would like to acknowledge the help and support of my advisors, Dr. Moody and Dr. Joner. They provided the guidance that made this research possible. I would also like to acknowledge all of the students who worked on this project before me and paved the way for my research. In addition, I would like to thank the Brigham Young University Department of Physics and Astronomy for funding this research.

I would also be remiss not to thank my wonderful wife Rochelle, whom I met and married during the course of this research and who has been my constant support. I am also grateful to my parents for raising me and to my firstborn child who has graciously decided to be born after the completion of this thesis.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. The SDSS Web Site is http://www.sdss.org/.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

## Chapter 1

## Introduction

Extragalactic astronomy relies on accurate distance measurements to map out the Universe and determine likely formation theories. However, it is incredibly difficult and time-consuming to obtain these distance measurements. We have developed a more accessible and precise method to measure distance using a set of photometric filters with sloped transmission values. Computational simulations indicate that this technique works with a standard deviation of $572 \mathrm{~km} \mathrm{~s}^{-1}$. Our precision improves with increasing equivalent width of the $\mathrm{H} \alpha$ line $(\lambda=656.3 \mathrm{~nm})$.

### 1.1 Motivation

Throughout the many sub-disciplines of astronomy, distance is a crucial measurement that is frequently difficult to ascertain. Although there are methods used to find distances to each astronomical object, they are typically not interchangeable. For example, we can find distances to stars by using their motion throughout the year relative to more distant background stars. This method is called parallax, and it is incredibly useful for nearby stars. However, galaxies are at distances so great that their motion (compared to background galaxies) is negligible, rendering the parallax method essentially useless for these objects. Even the methods used to measure distance to nearby galaxies
do not work for more distant galaxies and vice versa.
Those of us that study galaxies outside our own want to know these distances for several reasons. One major reason is to understand the nature of dark matter and the formation of the Universe. Using galactic distances, we create maps that outline how the Universe is structured. We find that galaxies formed in groups, creating large clusters with thin filaments connecting these clusters, surrounding massive voids that appear completely empty. However, our best theories about the nature of dark matter predict the presence of dwarf galaxies in the centers of these voids. So far, no dwarf galaxy has ever been discovered that resided within a void. As we shall soon see, the main distance measurement techniques are not well-suited to finding these dim galaxies. In response, we are developing our own method that is designed to work well for these dwarf galaxies.

### 1.2 Measuring Redshift

A term that I will use synonymously with distance is 'redshift'. This term comes from the apparent reddening that happens to light as it travels through space. As the Universe expands, the light passing through it is stretched as well, giving it a longer (redder) wavelength. This reddening is a function of distance, which means that we can find the distance to a galaxy given how red the light is. This should not be confused with the extinction and reddening of light passing through the interstellar medium, where short wavelength light is absorbed and scattered easier than the longer wavelengths. The equation to measure this redshift (or $z$ ), is as follows:

$$
\begin{equation*}
z=\frac{\lambda_{\text {obs }}-\lambda_{\text {emitted }}}{\lambda_{\text {emitted }}} \tag{1.1}
\end{equation*}
$$

In this equation, $\lambda_{\text {obs }}$ is the observed (redshifted) wavelength, whereas $\lambda_{\text {emitted }}$ is the original wavelength of the light when it was emitted from the source. Sometimes, this unitless number $z$ is replaced instead with $c z$, or the redshift $z$ multiplied by the speed of light $c$. This results in units of
$\mathrm{km} \mathrm{s}^{-1}$. Because of this conversion, extragalactic distances are expressed interchangeably in terms of either redshift or velocity.

### 1.2.1 Spectroscopy

Figure 1.1 This is a sample spectrum of a typical emission-line galaxy (SDSS J123000.98+520303.2), using data obtained from the Sloan Digital Sky Survey (SDSS) DR7 (Abazajian et al. 2009). Two prominent emission lines are labeled: the $\mathrm{H} \alpha$ line that we looked for in our ramp filters, as well as the [SII] line that increased our errors for high-redshift galaxies.

By passing light through a prism or grating, we can measure the relative flux of the light as a function of wavelength. This process is called spectroscopy. When we take the light from a galaxy, for example, and pass it through a prism, we see certain identifiable spectral features (as in Fig. 1.1). These correspond to atoms (e.g., hydrogen or oxygen) which are found in the galaxy observed. By heating up these atoms in a laboratory and measuring the emitted light, we find the original
wavelength of light when it was emitted from the galaxy. By comparing this to the wavelength we measured using Eq. 1.1, we can find the distance.

Spectroscopy is accurate, but it takes large amounts of light to be able to split it into component wavelengths. Gathering enough light requires using large telescopes (of which there are few and on which time is limited), and works better for bright objects (unlike distant dwarf galaxies). Additionally, spectroscopy is usually performed on one object at a time, and is not ideal for survey work.

### 1.2.2 Photometry

Photometry consists of taking images of objects through a telescope using specialized filters, then comparing these images to each other to gain insights. These filters transmit light at specific wavelengths while blocking all the light in other regions of the spectrum. Photometric measures of redshift rely on correlations between the brightness through certain filters to the redshift.

This is preferable over spectroscopy because it uses much smaller (and more readily available) telescopes, as well as working for multiple objects at once. However, these methods tend to have higher levels of error than spectroscopy.

The first photometric redshift method was developed by Baum (1962), which has since led to many other methods, including color-color diagrams (Koo (1985), Pello et al. (1996), Bolzonella et al. (2000)), linear regression (Connolly et al. 1995), template fitting (Loh \& Spillar 1986), prediction trees (Carrasco Kind \& Brunner 2013), and neural networks (Collister \& Lahav 2004). In addition to these methods, we note that Beck et al. (2016) used an empirical template method alongside SDSS data. Unfortunately, their standard of error ( $6150 \mathrm{~km} \mathrm{~s}^{-1}$ ) was similar in size to the voids we are working with, making their method unusable for void research.

In order to marry the benefits of spectroscopy and photometry, our team has designed a set of narrow-band filters (called 'ramp' filters) with variable transmission values that focus on the $\mathrm{H} \alpha$
emission line in galaxies with $0.01<z<0.03$ (Lesser et al. 2019). Because we are only trying to measure the distance to these galaxies (and do not need to see all of their spectral features), isolating this emission line allows us to conduct a photometric analog to spectroscopy, identifying the observed wavelength of this $\mathrm{H} \alpha$ line. By doing this, we have improved the precision by an order of magnitude (standard deviation of $572 \mathrm{~km} \mathrm{~s}^{-1}$ ), which makes it possible to conduct a survey of dwarf galaxy redshift to find any dwarf galaxies that might reside in the void.

### 1.2.3 Other Galactic Distance Measurements

Depending on the galaxy being observed, there are several other possible methods used to find the redshift. Each of these methods relies on comparisons between the absolute magnitude (or the brightness of the galaxy from a standard distance) and the apparent magnitude (or the brightness of the galaxy that we observe from Earth). These are related by the inverse-square law, which states that the apparent brightness is proportional to the absolute brightness divided by the distance squared.

All Type Ia supernovae (the explosion of a white dwarf star once it accretes enough mass to restart nuclear fusion) have approximately the same absolute magnitude at maximum light. Because of this, whenever a Type Ia supernova is observed in a distant galaxy, the absolute magnitude is immediately known. The apparent magnitude is measured with a telescope, and a comparison of the two using the inverse-square law provides the distance.

Another method is to use the Period-Luminosity relationship of Cepheid variable stars, which relates the period of a Cepheid to its absolute magnitude (Leavitt 1908). Again, after measuring the period and the apparent magnitude, a comparison of the apparent magnitude of a Cepheid in a distant galaxy with its known absolute magnitude will determine the distance.

For spiral galaxies, we can also use the Tully-Fisher Relation, which relates the width of emission lines with the total luminosity of a galaxy (Tully et al. 1975). If the total luminosity is
known, then this can be compared to the apparent magnitude to get a distance measurement.
These methods are highly useful and have been used to calibrate the relationship between redshift and distance. However, because of the nature of the dwarf galaxies we hope to study, it is not practical to use these methods.

## Chapter 2

## Methods

To measure redshift photometrically for galaxies with $0.01<z<0.03$, we decided to focus on the $\mathrm{H} \alpha$ emission line. We made this decision because the $\mathrm{H} \alpha$ line is a common, prominent spectral feature among galaxies. We created a set of three narrow-band photometric filters, for which the brightness in two of them is a function of the $\mathrm{H} \alpha$ line's wavelength. The ratio of these two filters correlates with redshift, meaning we can use these filters to accurately measure distance.

### 2.1 Filter Setup

We used three specialized photometric filters in our design. Two of these filters cover the same wavelength range (655-685 nm ) but their transmission levels are sloped oppositely. The first is called the "blue-sloping" or "BS" filter. This would ideally have $100 \%$ transmission at 655 nm and decrease linearly down to $0 \%$ transmission at 685 nm . The "red-sloping" or "RS" filter would be the opposite, with a linear slope from $0 \%$ transmission at 655 nm to $100 \%$ transmission at 685 nm . We call these 'ramp filters'. Because of this slope, the brightness through each filter is a function of the wavelength of the $\mathrm{H} \alpha$ emission line. The ratio of the light through these two filters tells us the wavelength of the $\mathrm{H} \alpha$ line, which we can use to find the redshift.

The third "continuum" filter is a 21 nm FWHM filter centered at 697 nm . This nearby filter has nearly $100 \%$ transmission, which gives us an approximation of the background light, which is then subtracted out of the other two filters. The trace for these three filters can be seen in Fig. 2.1.

Figure 2.1 This is the filter trace for our three photometric filters. The two on the left are our "ramp" filters, where the blue-sloping (or BS) filter starts near 100\% transmission for smaller wavelengths and decreases to $0 \%$ transmission for longer ones. The red-sloping (or RS) filter covers the same band of wavelengths as the BS filter, but the slope is opposite. The third "continuum" filter measures the background light, which is then subtracted from the other two filters. This figure is from Lesser et al. (2019).

### 2.2 Computational Modeling

We tested this method computationally using archival spectroscopic data from SDSS (see Abazajian et al. (2009)). These data came from 197 galaxies, which were each emission-line galaxies with strong $\mathrm{H} \alpha$ emission at a distance of $0.01<z<0.03$. For each of these galaxies, we knew the redshift (which is published by SDSS), as well as the location of the $\mathrm{H} \alpha$ line and its equivalent width. The spectrum of one of these galaxies can be found in Fig. 1.1.

### 2.2.1 Data Processing

We are interested in comparing the flux from the $\mathrm{H} \alpha$ line in the red-sloping (RS) filter to the flux of the $\mathrm{H} \alpha$ line in the blue-sloping (BS) filter. To find these flux values, we use the following steps:

1. We find the total flux of light through each filter, $F_{\text {total }}$, by integrating the flux at each wavelength $F(\lambda)$ times the filter's transmission at each wavelength $T(\lambda)$ over our wavelength range:

$$
\begin{equation*}
F_{\text {total }}=\int_{\lambda_{\text {start }}}^{\lambda_{\text {end }}} F(\lambda) T(\lambda) d \lambda \tag{2.1}
\end{equation*}
$$

2. Next, we need an average flux value for the continuum $\left(F_{C_{\text {avg }}}\right)$. We can find the average value by dividing the total flux by the width of the filter:

$$
\begin{equation*}
F_{C_{\text {avg }}}=\frac{F_{C_{\text {total }}}}{21 \mathrm{~nm}} \tag{2.2}
\end{equation*}
$$

3. We then measure the continuum's contribution to each ramp filter's flux $\left(F_{R_{C}}\right)$ by inserting $F_{C_{\text {avg }}}$ in place of $F(\lambda)$ in Eq. 2.1, using $T_{R}(\lambda)$ as the transmission values of the ramp filter:

$$
\begin{equation*}
F_{R_{C}}=\int_{\lambda_{\text {start }}}^{\lambda_{\text {end }}} F_{C_{\text {avg }}} T_{R}(\lambda) d \lambda \tag{2.3}
\end{equation*}
$$

4. The flux from the $\mathrm{H} \alpha$ line in each ramp filter $\left(F_{R_{H \alpha}}\right)$ is the difference between each ramp filter's total flux ( $F_{R_{\text {total }}}$ ) and continuum flux $\left(F_{R_{C}}\right)$ :

$$
\begin{equation*}
F_{R_{H \alpha}}=F_{R_{\text {total }}}-F_{R_{C}} \tag{2.4}
\end{equation*}
$$

5. The result of step 4 is the flux from the $\mathrm{H} \alpha$ line for each of our ramp filters. By comparing the ratio of the BS filter's flux to the RS filter's flux (the $B S / R S$ ratio) and comparing the result to the published redshifts for our galaxies, we establish the relationship between $B S / R S$ and $z$. This relationship is further explored in Sec. 3.1.

Figure 2.2 This is a filter trace for an idealized version of the filters found in Fig. 2.1. In this setup, the slopes on the BS and RS filters would be perfectly linear, and the continuum filter would have $100 \%$ transmission for its wavelength range.

### 2.2.2 Idealized Filter Sets

To show that our methodology was sound in the absence of imperfections, we first used an idealized version (Fig 2.2) of our actual filters (given in Fig 2.1).

While doing this method, we found a strong relationship between the $B S / R S$ ratio and the redshift. However, for galaxies with $z>0.018$, the [SII] emission line (doublet at $\lambda=671.6 \mathrm{~nm}$
and 673.1 nm , placing it just to the red side of $\mathrm{H} \alpha$ ) is redshifted into the continuum filter. This affects our continuum measurement, and increases the error of our method. We explore the extent to which this affects our results in Chapter 3.

To adjust for this, we tried many other filter configurations, including:

- Shifting the current continuum filter so that it covers a new wavelength range of 625 nm to 645 nm .
- Two continuum filters, ranging from 625 nm to 645 nm on the blue side and from 720 nm to 740 nm on the red side. In the model, these were exposed separately to estimate the slope of the continuum.
- Two continuum filters, ranging from 625 nm to 645 nm on the blue side and from 720 nm to 740 nm on the red side. These were exposed together, giving one reading for the continuum.
- One large continuum filter, with a wavelength range of 620 nm to 720 nm .
- Narrower or wider variants of the same continuum filter (still centered on 697 nm ).

Despite the change in the filters, we processed the data as outlined in 2.2.1. These configurations resulted in varying levels of success, with the best results coming from the first option. As a result, we are purchasing a new continuum filter that we hope will increase the precision of our measurements.

### 2.2.3 Realistic Filter Sets

After determining that our method works in ideal conditions, we repeated the computational modeling (following the steps in Sec. 2.2.1), using the transmission values of our actual (imperfect) filters (as seen in Fig 2.1). Despite the imperfections in our filters, the relationship between $B S / R S$ and $z$ remained strong and we believe we can accurately measure redshift using this method.

## Chapter 3

## Results and Conclusions

We found a strong relationship between the ratios of flux through our filters (the BS/RS ratio) and the redshift, and we found that we can predict the redshift with a standard deviation of $572 \mathrm{~km} \mathrm{~s}^{-1}$, an order of magnitude more precise than similar photometric redshift methods. This relationship improves as a function of increasing $\mathrm{H} \alpha$ equivalent width, with the standard deviation dropping to $252 \mathrm{~km} \mathrm{~s}^{-1}$ when the equivalent width of $\mathrm{H} \alpha$ was over $40 \AA$. These computational results are consistent with our observations. This method requires more observational testing, and can be improved with a different continuum filter.

### 3.1 Results and Analysis

For each of our 197 archival galaxies, the calculated BS/RS ratio was compared to the redshift $c z$ published by SDSS as a part of DR7 (Abazajian et al. 2009). The derived relationship is given by Eq. 3.1 below, and is graphed in Fig. 3.1.

$$
\begin{equation*}
c z=6728.24\left(\frac{B S}{R S}\right)^{3}-17403.27\left(\frac{B S}{R S}\right)^{2}+8202.00\left(\frac{B S}{R S}\right)+7201.14 \tag{3.1}
\end{equation*}
$$

This relationship is valid for galaxies with $c z$ values between 3000 and $9000 \mathrm{~km} \mathrm{~s}^{-1}$, and has
a standard deviation of $572 \mathrm{~km} \mathrm{~s}^{-1}$. The prominent 'bump' in Fig. 3.1 at $\frac{B S}{R S} \approx 0.8$ is a known problem caused when the [SII] line is redshifted from the BS and RS filters into the continuum filter. Our proposed solution to this issue is discussed further in Sec. 3.2.

In addition to this computational modeling, we have used these filters to observe 16 active Seyfert galaxies. Our observational results closely match our computational models, indicating that our models are accurate. The results from this survey are graphed alongside the computational data in Fig. 3.1 as the "Seyfert Sample" and can also be found in Table 3.2.

Table 3.1 contains data from the 197 galaxies. The first 5 columns are published by SDSS in Abazajian et al. (2009), while the last 4 columns were calculated as part of the present investigation. The strength of the relationship between the $\frac{B S}{R S}$ ratio and $c z$ depended heavily upon the equivalent width of the $\mathrm{H} \alpha$ line, as shown in Fig. 3.2. We divided the galaxies into four groups: those with $\mathrm{H} \alpha$ equivalent width from 0 to $9 \AA, 10$ to $19 \AA, 20$ to $39 \AA$, and greater than $40 \AA$. The standard deviations for each of these bins, respectively, are $619,464,346$, and $252 \mathrm{~km} \mathrm{~s}^{-1}$.

Figure 3.1 The relationship between the BS/RS ratio and the $c z$ for galaxies with 3000 $\mathrm{km} \mathrm{s}^{-1}<c z<9000 \mathrm{~km} \mathrm{~s}^{-1}$ can be described well with a third-order polynomial fit. The data plotted here represent all 197 SDSS galaxies (separated by equivalent width of the $\mathrm{H} \alpha$ line), as well as 16 Seyfert galaxies we observed with these filters. This figure is from Lesser et al. (2019).

Figure 3.2 The strength of the relationship between the BS/RS ratio and $c z$ increases for galaxies where the equivalent width of the $\mathrm{H} \alpha$ line is stronger. In fact, as the equivalent width increases, the relationship becomes more and more linear. This figure is from Lesser et al. (2019).

### 3.2 Future Work

Our current continuum filter is a 21 nm FWHM filter centered at 697 nm . This works decently well to remove the continuum from our BS and RS filters, but for galaxies with $z>0.018$ the [SII] line is redshifted into the continuum filter and greatly increases our errors. After computationally modeling many different filter layouts to find a suitable replacement (see Sec. 2.2.2), we found that the best continuum filter would be identical to our current figure, but shifted blueward of our BS and RS filters. We are going to obtain this filter to use in future survey work.

Our preliminary observational results support the accuracy of our models, but more observations with these filters are needed to confirm the method. Future observations with these filters should compare calculated $c z$ values with those obtained spectroscopically to verify their validity.

As described in Chapter 1, these filters are useful for survey work, particularly for dwarf galaxies within voids. We plan to one day use these filters to conduct a survey of nearby voids in an effort to identify the first known void galaxy.
